TITLE: Some problems of aluminium production

PERIODICAL: Hutnické listy, 1961, No.10, pp.710-715

TEXT: Present aluminium production in Czechoslovakia does not meet steadily increasing demands and projects for the building of additional plant, with special reference to available raw materials and their location, are discussed. The problem is presented in three main sections: 1) Production of aluminium oxide, 2) its conversion, by electrolysis, to aluminium, and 3) possibility of aluminium production by an electric furnace. Ad 1) Two processes are available for aluminium oxide production: the Bayer process which is only applicable to high-grade, SiO<sub>2</sub>-poor bauxites and the older fusion process which is limited to lower-grade bauxites. The aluminium works in Czechoslovakia are based on aluminium oxide, produced by the fusion process from lower-grade Hungarian bauxite. The process is more complicated, energy expenditure is higher and the material is not very well suited for electroconductive aluminium. A special desilication process is

Card 1/5

Some problems of aluminium production 2/034/61/000/010/001/002  
E112/E553

inserted in the Czechoslovak plant. It is suggested that lower grade bauxites may be processed by a combination of the Bayer and fusion methods, but difficulties may be encountered at some stages of the process, particularly during filtration of the residues of iron oxides. Production costs of aluminium oxide and aluminium are itemized, indicating that raw material costs are the decisive factor for aluminium oxide, while electric energy is the essential factor for aluminium. ✓

<u>Aluminium:</u>	
Raw-material .....	56% (from 80% Al <sub>2</sub> O <sub>3</sub> )
Electric energy .....	22%
Wages .....	3.9%
Maintenance .....	11.2%
Special costs .....	2.2%
Works overheads .....	4.7%
<u>Total</u>	<u>100.0%</u>

<u>Aluminium oxide:</u>	
Raw materials (bauxite) .....	28%
Energy (electric, steam, water, air) .....	29%
Wages .....	5.5%
Maintenance .....	37.5%
<u>Total</u>	<u>100.0%</u>

The complex nature of the aluminium process is mirrored by high maintenance costs. Supplies of Hungarian bauxite are limited and domestic raw materials will have to be investigated. The kaolinites from the North Bohemian coal basin (dry contents: 30-35% Al<sub>2</sub>O<sub>3</sub>, 40-45% SiO<sub>2</sub>, 2-10% Fe<sub>2</sub>O<sub>3</sub>, 1-6% TiO<sub>2</sub>) are, theoretically, of interest because of the relatively high Al content, but the high SiO<sub>2</sub> ratio, on the other hand, would necessitate a preliminary treatment. Although the process would be complicated, it is estimated that costs would not exceed that of the fusion process from low-grade bauxites. Reliable data could, however, be established only after prolonged pilot-plane experiments. It is generally estimated that aluminium production from domestic materials would require a period from 8 to 10 years

Card 3/5

Some problems of aluminium production Z/034/61/000/010/001/002  
E112/E553

before it could be established successfully. The purchase of bauxite from overseas may be necessary. Ad 2) The electrolytic process for aluminium production from  $Al_2O_3$  is described in detail. Types of electrolytic cells are reviewed. Aluminium works ought to be built in the immediate vicinity of cheap electricity supply. The problem is complicated by the fact that power stations in Czechoslovakia are located in the more densely populated agricultural districts. The effects of the toxic anodic exhalations have to be carefully examined. These considerations would suggest that production units should not exceed an annual production of 100 000 tons of Al. In order to improve the economy of the electrolytic process, the use of semiconductor rectifiers and large electrolytic cells with an intensity of 100 kA are recommended. Ad 3) Discussion of electrothermic process. It should be possible, on theoretical considerations, to meet the entire Czechoslovak requirements of aluminium alloys (silumine, an alloy with silicium) from domestic raw materials (low-grade kaolines) by using the electric arc process. The construction of a high-capacity single-phase arc furnace remains the main problem. The purchase of a pilot-plant furnace from Eastern Germany is

Card 4/5

Some problems of aluminium production Z/034/61/000/010/001/002  
E112/E553

recommended. The results of some Soviet experiments with an  
experimental furnace of 16 MVA should be awaited.

TITLE:

Analysis of the First Movements of the Seismic Waves Recorded on Seismographs

PERIODICAL:

Acta geophysica polonica, 1959, Vol 7, Nr 2, pp 136-164 (POL)

ABSTRACT:

New problems developing in modern seismologic science require in many cases accurate knowledge of the true values of the amplitudes and periods of the first recorded movements of the seismic wave. These values are, as a rule, strongly deformed by instruments. Complete elimination of these distortions by computation is impossible at present owing to our lack of knowledge of the analytical shape of true ground movement. From recent research work it appears that the frequency characteristics computed for first ground vibrations do not show major dissimilarities. In order to simplify computation, a sinusoidal form of the ground vibrations will therefore be assumed in this investigation. Recent experimental material

Card 1/3

POL/26-7-2-4/18

Analysis of the First Movements of the Seismic Waves Recorded on Seismographs

confirm the correctness of such an assumption. The purpose of this investigation is to examine the deformations in periods and first amplitudes caused by seismographs of various types. Two types of seismographs were examined. For the first type, seismographs with mechanical recording, the character of period and amplitude deformations in the first movement is shown in figure 15, the seismograph used being one with a free vibration period of 6 seconds and a damping constant of 0.1. The other type of apparatus investigated is the seismograph with galvanometric recording. The frequency characteristics in this case are illustrated in figures 19, 20, and 21. A full English summary appears on pp 157-164. There are 21 graphs and 7 references, 4 of which are Soviet, 1 Czech, 1 French, and 1 Polish

TITLE: Certain factors are given for calculations of the mean reactive voltage upon assumption that the current changes in the commutator coil are linear

SOURCE: Elektrotechnicky obzor, v. 55, no. 2, 1966, 78-82

TOPIC TAGS: electronic commutator, voltage regulation, direct current, electric motor, armature, magnetic field

ABSTRACT: Small and medium DC machines<sup>29</sup> usually are equipped with commutating poles having flat pole-shoes which generate a magnetic field which neutralizes the mean value of the reactive voltage. That voltage can be calculated with given equations. To simplify the calculation, Richter introduced the factors  $\mathcal{K}$  and  $\mathcal{K}'$ . Calculated values for quite a restricted number of cases were published by him. At the Institute the values of  $\mathcal{K}$  and  $\mathcal{K}'$  were calculated for all used armature windings for small and medium DC motors, and those values are presented in annexed tables. This paper was presented by Professor, Engineer J. Chladek. Orig. art. has: 4 figures, 15 formulas and 6 tables. [Based on author's Eng. abstract] [JPRS: 35,327]

TITLE: ~~The Dependence of the~~ Hardness Distribution on the  
Microstructure in the Head of Surface-Hardened Rails  
(Souvislost průběhu tvrdosti v hlavě povrchově kalených  
kolejnic s mikrostrukturou)

PERIODICAL: Hutnické Listy, 1959, Nr 7, pp 649-656 (Czechoslovakia)

ABSTRACT: Czechoslovak Metallurgical Report, Nr 7, July, 1959.  
One of the possible methods of heat treatment of rails  
is to harden the surface by quenching the railhead from the  
temperature of the rail at the end of the rolling process  
and to temper it by means of the internal heat of the  
core of the rail and the railhead. This method is  
applicable both for hardening the ends of rails and also  
for hardening the running surface of the railhead.  
Experience gained during 1953 and 1954 at the Vítkovice  
Iron Works (Ref 1) has shown that the hardness does not  
decrease continuously with the depth as it should; at a  
certain depth below the running surface the drop in  
hardness stops and there is a rise in the hardness with  
depth which is followed by a continuous slow drop in  
Card 1/6 hardness towards the centre of the railhead. Since it is ✓

in the Head of Surface-Hardened Rails

known from literature (Ref 2) that, in surface hardened rails, the surface hardened layer frequently peels off and there may even be slip of the hardened layer in the longitudinal direction followed by chipping off, the author of this paper considered it of interest to investigate the cause of the transient increase in hardness and the relation between this increase and the applied hardening process. Most authors do not mention the presence of a transient increase in hardness at a certain depth below the running surface, however, H. O'Neill (Ref 3) reported that he detected a transient increase in the hardness of surface hardened rails with carbon contents of 0.50 to 0.55% and manganese contents of 1.10 to 1.20%. His results are reproduced in the graph, Fig 1, p 649. The author of this paper carried out tests under laboratory and normal operation conditions. The equipment used in the experiments was described in an earlier paper. It consisted of a sheet steel box, one side of which was provided with holes, the

in the Head of Surface-Hardened Rails

shapes of which were adapted to the shape of the railhead. Asbestos lining prevented penetration of the water to the vertical and the bottom parts of the rail. In the laboratory experiments, rail sections of about 500 mm length were used with chemical compositions as enumerated in Table 1; for two of these the hardness as a function of the depth is graphed in Fig 2, whereby one of the rails was quenched for 27 secs from 830°C, the other was quenched for 45 secs from 830°C. For the spots designated by arrows in this graph, microstructure photographs were taken which are reproduced in Figs 3 and 4. Comparison of the microstructure with the hardness characteristic shows that the zone of maximum hardness, directly below the running surface, consists of pure sorbite (Figs 3a, 4a), whilst at the spots of relative minimum hardness the structure was found to be bainitic. The beginning of the second increase in hardness is characterized by the appearance of fine pearlite (troostite), Figs 3b and 4b, in continuously increasing quantities until fine pearlite is the only structural component in the region of the relative

hardness maximum, Fig 3e. Then, towards the core of the railhead, the inter-lamellar distance increases gradually and so does the quantity of pro-eutectic ferrite at the grain boundaries. According to O'Neill, the formation of a pronounced bainitic zone is due to the transformation characteristics of a given steel during continuous cooling. If this were true, a similar phenomenon should occur in Jominy test rods made of the same material. However, results, shown in Fig 5, confirm the known fact that for these steels Jominy test specimens do not show a transient increase in hardness, i.e. that the explanation of O'Neill is incorrect. On the basis of the obtained results it is concluded that:

1) A condition for the occurrence of a pronounced bainite zone is the existence of an austenite zone (possibly with a certain quantity of bainite) under the martensite zone at the instant when the quenching is stopped. During subsequent tempering by the internal heat of the rail, this austenite becomes transformed into bainite. Thus,

Card 4/6

✓

CZECH/34-59-7-22/22

The Dependence of the Hardness Distribution on the Microstructure  
in the Head of Surface-Hardened Rails

a determining factor on whether a pronounced bainite zone occurs is the mutual relation between the quenching time and the hardenability of the used steel.

2) The formation of a relative minimum and a relative maximum is due to the fact that during tempering the hardness of the bainite drops faster than that of fine pearlite so that even after a few seconds the hardness of the bainite will be lower than the hardness of the fine pearlite.

3) The occurrence of a relative minimum and a relative maximum on the hardness curves in the cross-section of a surface hardened rail is not a necessary condition for the existence of a relative maximum and a relative minimum on the hardness curve obtained on a Jominy specimen hardened by current methods. However, if the hardening time is shortened, Jominy specimens will also show relative minima and relative maxima of the hardness.

4) The formation of a bainite zone, and thus also the formation of a relative minimum and maximum of hardness,

Card 5/6 can be prevented either by increasing the quenching ✓

The Dependence of the Hardness Distribution on the Microstructure  
in the Head of Surface-Hardened Rails

duration (if this is possible without exceeding the maximum permissible hardness of the tempered martensite, which should not exceed 400 HB), or by reducing the hardenability of the used steel to  $D_1 \leq 35$  mm.

5) Practical experience gained in 2 1/2 years rail operation indicates that the presence of the bainite zone in the hardened ends of rails does not affect adversely the rail performance on the track.

## ABSTRACT:

Vacuum metallurgy offers both a better quality product and a more economical production method. Rails made from degassed steel and air-cooled after rolling show an improved tensile strength, higher toughness, and better wear resistance than rails made from ordinary steel and cooled slowly in pits. Certain differences found in the properties of samples taken from various spots in a single billet are explained by changes in chemical composition in the respective parts of the billet. Practical experience with the rails shows that double the length of life can be expected from these rails than from those made from carbon steel that was not degassed.
